Common Polymorphisms in Angiogenesis

Michael S. Rogers and Robert J. D'Amato

Correspondence: michael.rogers@childrens.harvard.edu

A wide variety of diseases have a significant genetic component, including major causes of morbidity and mortality in the western world. Many of these diseases are also angiogenesis dependent. In humans, common polymorphisms, although more subtle in effect than rare mutations that cause Mendelian disease, are expected to have greater overall effects on human disease. Thus, common polymorphisms in angiogenesis-regulating genes may affect the response to an angiogenic stimulus and thereby affect susceptibility to or progression of such diseases. Candidate gene studies have identified several associations between angiogenesis gene polymorphisms and disease. Similarly, emerging pharmacogenomic evidence indicates that several angiogenesis-regulating polymorphisms may predict response to therapy. In contrast, genome-wide association studies have identified only a few risk alleles in obvious angiogenesis genes. As in other traits, regulatory polymorphisms appear to dominate the landscape of angiogenic responsiveness. Rodent assays, including the mouse corneal micropocket assay, tumor models, and a macular degeneration model have allowed the identification and comparison of loci that directly affect the trait. Complementarity between human and animal approaches will allow increased understanding of the genetic basis for angiogenesis-dependent disease.

Angiogenesis is the process by which new blood vessels are formed from existing vessels. Angiogenesis is regulated by a wide variety of endogenous molecules, most of which have additional functions. It is often implicitly assumed that a given angiogenic stimulus (hypoxia, VEGF gradient, etc.) will produce the same response. However, such an assumption ignores the possibility of quantitative and even qualitative differences in angiogenic response resulting from genetic variation. Angiogenesis-regulating genetic variation affects the ability of an organism to respond to angiogenic stimuli. Thus, it may

affect susceptibility to, or the progression of, angiogenesis-dependent disease.

IDENTIFYING ANGIOGENESIS-REGULATING GENETIC VARIATION

Genetic variations that alter angiogenic responsiveness can be detected by a variety of methods. In animals, there are several models of angiogenesis in which variation has been observed, and in many cases strain-related differences among these models are correlated. The best studied of these is the corneal micropocket assay where the amount of growth factor required to

elicit a given response can vary by more than 10-fold between different strains of mice.

In the case of humans, assays have not been identified that can measure angiogenic responsiveness. Nevertheless, there are a number of mechanisms by which angiogenesis response alleles might be identified. There are several Mendelian diseases that result in telangiectasia and other vascular abnormalities. However, such traits often reduce reproductive fitness, are thus not common in the population, and as a result contribute little to overall human disease. However, they can provide leads for candidate genes for other studies. In candidate gene studies, polymorphisms in genes previously identified as being involved in angiogenesis are tested for their association with the trait in question. Importantly, because it begins with candidate genes, this method does not allow novel genes or pathways involved in angiogenesis to be discovered. In contrast, advances in genetics have allowed performance of genome-wide association studies (GWASs). Currently, these studies are performed by testing tag single nucleotide polymorphisms (SNPs) for their association with a phenotype in question. Generally, such studies require very large sample sizes to overcome statistical problems with multiple testing and imperfect linkage disequilibrium implicit in the tag SNP approach. As a result, detailed phenotyping and subgroup analysis are not typically available in GWASs; however, this method allows the identification of novel genes associated with a particular trait in the general population.

CANDIDATE GENE STUDIES IN HUMANS

For the reasons outlined above, the vast majority of angiogenesis genetic studies in humans have taken a candidate gene approach; that is, they have focused on asking whether polymorphisms in genes associated with angiogenesis can affect angiogenesis-dependent disease. However, the converse has not been done; that is, the question of which polymorphisms most strongly affect angiogenesis has not been asked. Thus, it is possible that the common human polymorphisms that most strongly affect

angiogenesis have not been identified. As a result, the overall effect of genetic polymorphism on angiogenesis-dependent disease has not yet been rigorously tested. Nevertheless, polymorphisms in several angiogenesis-related genes have been shown to affect disease susceptibility and/or progression. For these genes we outline (1) the role of a given gene in angiogenesis, (2) the nature of observed common polymorphisms in that gene and any functional consequences known, (3) the association of polymorphisms with known angiogenesis-dependent diseases, and (4) whether the observed correlation seems likely to be mediated by changes in the angiogenic response. In the majority of cases, polymorphisms associated with differences in angiogenic response are regulatory in nature. This is consistent with the observation in expression quantitative trait locus (eQTL) studies that regulatory polymorphisms dominate the variation landscape (Schadt et al. 2003; Stranger et al. 2007; Cahan et al. 2009).

These polymorphisms have occasionally been associated with conditions that are not typically believed to be angiogenesis related. For example, a polymorphism in the VEGF gene has been associated with kidney function in chronic kidney disease. Although this may indicate that angiogenesis has an as-yet underappreciated role in kidney disease, it is possible that the regulation of kidney development and podocyte function provided by VEGF is the mechanism by which this polymorphism affects kidney disease (Kottgen et al. 2010). We will typically not highlight such a role because the gene in question often has other nonangiogenesis-related functions. Similarly, we will not highlight cases where association studies have failed, because such failures are often a result of power issues.

In candidate gene studies, polymorphisms in VEGF, VEGFR2, eNOS, HIF-1 α , MMP2, TIMP3, IL-8, CXCR2, and α v and β 3 integrins are clearly angiogenesis-dependent disease associated and upon further study those in PAR-1, galectin-3, and adrenomedullin are likely to be connected. Less certain are associations with polymorphisms in BDNF, thrombospondin,

angiopoietins, and TIE2, whereas associations with endostatin and erythropoietin polymorphisms are unlikely to be biologically relevant. In the cases of polymorphisms in VEGFR1, IL-6, IL-10, TNF- α , other MMPs, TIMPs, clotting cascade proteases, and BMP-9 pathway members there appear to be associations with disease; however, it is unclear whether these are angiogenesis mediated or not.

VEGF

Vascular endothelial growth factor (VEGF) was originally described as vascular permeability factor and is a relatively specific endothelial cell mitogen and chemotactic factor that is important in a wide variety of angiogenic processes. In addition, it is also involved in kidney and lung function as well as serving as a survival

factor for neuronal cells. The gene is critical to life; thus, even the haploid state results in embryonic lethality in mice. Nevertheless, the triploid state appears to be compatible with life in humans (Mandal et al. 2007).

The VEGF gene is highly polymorphic, with hundreds of polymorphisms currently annotated in dbSNP (Fig. 1). Of these there are dozens with a minor allele frequency > 1%. These are organized into three major regions of linkage disequilibrium, one well upstream of the transcription start point, one encompassing the promoter and the first six exons, and a third covering the last two exons, including the 3' UTR (Garcia-Closas et al. 2007). Little is known about the first block; however, one study implicates a polymorphism in this region in bladder cancer susceptibility (Garcia-Closas et al. 2007). The third (3' UTR) region contains one well-studied

Figure 1. VEGF gene polymorphisms. The VEGF gene and surrounding sequence are outlined. Each + represents a polymorphic site. The position of the full-length transcript, exons, and longest splice form are diagrammed. The position of commonly assessed polymorphisms according to both of the commonly used numbering schemes (from the transcription start point “mRNA,” and from the translation start point “ATG”) are indicated. The three major regions of linkage disequilibrium are shown, together with common haplotypes. The haplotype numbering schemes of Stevens (s) (Stevens et al. 2003), Awata (a) (Awata et al. 2005), Garcia-Closas (g) (Garcia-Closas et al. 2007), and McKay (m) (McKay et al. 2009) are indicated, as well as the frequency of the haplotypes in the indicated control populations. Shaded genotypes indicate a difference with the chimpanzee or orangutan genome, suggesting that the shaded allele is the derived allele. The position of the 936C > T polymorphism in the 3' UTR is also indicated.

M.S. Rogers and R.J. D'Amato

polymorphism, 936C > T (rs3025039). In carriers of the 936T allele (heterozygous or homozygous) in the 3' UTR, the VEGF plasma level is, on average, one-third that of noncarriers (Renner et al. 2000).

As outlined in Figure 1, the second region of linkage disequilibrium, which contains the VEGF gene promoter, is complex. It has at least four major common haplotypes, as well as several minor haplotypes, resulting in more than 10 common promoter genotypes in humans. There have been several studies that have assessed the effect of differing haplotypes on promoter activity. However, the effect of polymorphisms on gene promoter activity and RNA levels seems to be cell-type and stimulus specific. Nevertheless, circulating VEGF levels are highly heritable (Pantsulaia et al. 2004) and correlations have been found between genotype in both the second and third regions of LD and VEGF levels in multiple tissues and fluids, as well as with microvessel density, although there are conflicting reports as well. For example, multiple studies have found no correlation between cancer patient serum VEGF and VEGF gene polymorphisms. This is unsurprising because any genetic signal is likely to be lost in tumor-induced variability. Also, for a tumor to grow it must have first produced sufficient angiogenic factor to induce angiogenesis, and this requirement does not change with VEGF genotype. In the case of normal controls, conflicting reports about the effect of a given polymorphism or haplotype are likely because the effect of genotype on VEGF expression is cell-type and stimulus specific. This situation is further complicated by the fact that individual polymorphisms are often studied in isolation, but are not inherited in isolation. Rather, they are inherited as part of a larger haplotype, and thus individuals grouped according to genotype at a single polymorphism are actually mixtures of individuals who bear different haplotypes of the VEGF promoter.

There are currently more than 350 studies examining the association between VEGF genotype and human disease (Table 1). However, many of these studies are difficult to interpret because they examine only individual SNP

genotypes, rather than looking at haplotypes. As a result, it is possible that many studies may fail to see an association as a result of dilution of affected with unaffected individuals. For example, in early studies, the C allele of the 405G > C polymorphism, which is contained in haplotype 1, was associated with endometriosis susceptibility. In contrast, the T allele of the -460T > C polymorphism, which is contained in both haplotypes 1 and 2, fails to show significant association despite a promising trend (Bhanoori et al. 2005). This is likely because of a dilution of the "active" haplotype 1 with haplotype 2, and later studies have amply confirmed the importance of VEGF promoter polymorphisms in endometriosis.

To discriminate the major genotypes in the VEGF promoter, it is necessary to genotype at least three polymorphisms (e.g., -1540/-2578/rs699947, -116/-1154/rs1570360, and 405/-634/rs2010963). In addition, the +936 (rs3025039) polymorphism in the 3' UTR should be tested. In general, current tag SNP approaches seem to be less powerful in detecting association, as such approaches fail when assessment of "functional" SNPs succeeds. For example, from studies on traditional SNPs there is substantial although not uniform evidence that VEGF polymorphisms play a small role in susceptibility to macular degeneration (Galan et al. 2010) and a somewhat stronger role in progression to the wet form of the disease (Francis et al. 2009). However, neither of the studies taking a tag SNP approach (Hanaoka et al. 2009; Zablotna et al. 2010) have noted the association.

In addition to macular degeneration, VEGF gene polymorphisms have been associated with a wide variety of diseases and other phenotypes (Table 1). Unsurprisingly, haplotype 3 has even been associated with an increase in overall lifespan in an Italian population (Del Bo et al. 2008). As might be expected, VEGF polymorphisms are associated with a wide variety of cancer-related phenotypes, including overall incidence of cancer, as well as thrombotic complications in some, but not all cancer types. Importantly, VEGF may have different (or no) effects at different times in disease progression. For example, in the case of cancer, VEGF may

Table 1. Phenotypes in which VEGF polymorphisms have been studied

Life span	Psoriatic arthritis
Cancer thrombosis	Renal graft survival
Glioma/glioblastoma	Heart transplant acute rejection
Head and neck cancer	Acute respiratory distress syndrome
Nasopharyngeal carcinoma	(–)Type 2 diabetes
Thyroid carcinoma	Type 1 diabetes
Oral cancer	Diabetic neuropathy
Laryngeal squamous cell carcinoma	Diabetic nephropathy
Esophageal cancer	Diabetic retinopathy
Esophagogastric junction cancer	Retinopathy of prematurity
Gastric cancer	Age-related macular degeneration
Colorectal cancer	Ptergium
Hepatocellular carcinoma	Ocular pseudoxanthoma elasticum
Gallbladder cancer	VO ₂ max

Boldface text indicates that the bulk of evidence confirms an association between one or more VEGF polymorphisms and the risk, severity, progression (including metastasis), age of onset, or outcome for the indicated trait. A (–) indicates that the bulk of evidence shows no association of the trait with the VEGF polymorphism(s) studied. *Italic* text indicates conflicting evidence. For other listed traits, only a single report is available and, thus, the association should be considered unconfirmed. References available from the authors upon request.

play a minor role in tumor initiation, but a significant role in progression or metastasis. Melanoma is a rare example of a cancer in which the pre-angiogenic lesion is readily detected and is thus instructive. VEGF polymorphisms have not been associated with risk of disease; however, a low-expressing VEGF haplotype is associated with thin (i.e., nonangiogenic) melanoma (Howell et al. 2002). This observation is consistent with the notion that angiogenesis polymorphisms play a less important role in tumor initiation than in tumor progression and metastasis.

In addition, gene–gene interactions can affect whether a particular polymorphism affects cancer risk. For example, several meta-analyses have shown that the risk of developing breast cancer is not associated with genotype in the +936C > T polymorphism in the general population. However, in BRCA1 carriers the low-VEGF T-allele confers protection from disease (Jakubowska et al. 2008). Similarly, although large case-control studies have failed to find an association between prostate cancer risk and VEGF polymorphisms (Jacobs et al. 2008), when gene–gene interactions are considered, several smaller studies have shown that VEGF polymorphisms can play a role in disease risk or aggressiveness (Sfar et al. 2010; Van-Cleave et al. 2010).

Association between a disease and VEGF polymorphisms does not necessarily mean that the disease is angiogenesis dependent. For example, hydrocele development in lymphatic

filariasis patients is strongly affected by genotype at the –460 polymorphism. However, because this condition is characterized by extensive vascular leak, it is likely that the effect is mediated by induction of vascular permeability by VEGF, rather than by angiogenesis. Another example arose from the observation that mice with a deletion of the hypoxia response element in the VEGF promoter develop adult-onset motor neuron degeneration reminiscent of amyotrophic lateral sclerosis (ALS) (Oosthuysen et al. 2001). This clue led to the discovery that VEGF is a survival factor for neural cells. Thus, the observation that the 22578AA genotype is associated with ALS in men does not necessarily indicate that angiogenesis is involved in ALS; rather, it suggests that VEGF protects neurons from the insults that lead to neuronal degeneration in the disease. Similarly, development of type 1 diabetes has been associated with particular genotypes in the VEGF gene (Del Bo et al. 2006). However, long distance linkage has been demonstrated between the VEGF gene and the adjacent HLA complex (Chen et al. 2009). Given the very strong association between HLA genotype and type 1 diabetes, it is possible that the VEGF association results from linkage disequilibrium with the HLA complex, rather than from differences in VEGF regulation.

Pharmacogenomic studies on angiogenesis inhibitors are currently somewhat rare. However, one group has identified an association between VEGF promoter polymorphisms and

breast cancer response to bevacizumab, with genotypes consistent with haplotype 4 associated with dramatic extension of overall survival (Schneider et al. 2008). In addition, genotypes consistent with haplotype 1 reduced the incidence of treatment-associated hypertension (Schneider et al. 2008), an observation that has since been confirmed (Etienne-Grimaldi et al. 2010), and extended to sunitinib-treated metastatic renal cancer patients (Kim et al. 2009b). In colorectal cancer, VEGF promoter polymorphisms predict response and time to progression with anti-VEGF therapy (Pander et al. 2010). However, promoter polymorphisms have similar predictive power with chemotherapy regimens lacking an anti-VEGF component (Chen et al. 2010a). Similar results are obtained in lung cancer (Heist et al. 2008). This suggests either that current cytotoxic chemotherapeutic regimens have a significant antiangiogenic component even in the absence of a targeted angiogenesis inhibitor, or that growth in an environment with altered VEGF availability affects the biological characteristics of a tumor in a way that alters its response to chemotherapy.

VEGFR2

VEGFR2 is a tyrosine kinase receptor containing several nonsynonymous SNPs of unknown functional significance, and several regulatory SNPs. For example, the $-604C$ allele decreases transcriptional activity and protects against age-related macular degeneration (Galan et al. 2010). In addition, there is evidence of gene–gene interactions with VEGF genotype (Van-Cleave et al. 2010). However, studies to identify VEGFR2 polymorphisms that might predict Lucentis response were negative (Kloeckener-Gruissem et al. 2011).

In contrast, in colon cancer, the $-604CC$ promoter genotype is associated with increased microvessel density and decreased survival, whereas the translationally silent $1192C > T$ polymorphism is associated with decreased microvessel density and increased survival (Hansen et al. 2010). A tag SNP approach has generated some evidence for association

between glioblastoma and VEGFR2 genotype (Andersson et al. 2010). However, breast and lung cancer studies are uniformly negative. In a small study of prostate cancer, H472Q affects the frequency of sorafenib-induced side effects, which are in turn predictive of patient survival (Jain et al. 2010). Similarly, in CML the H472Q polymorphism has been shown to affect the likelihood of complete cytogenetic response to imatinib therapy as well as the odds of treatment failure (Kim et al. 2010).

The 472Q variant is overrepresented in endurance athletes, where it is also associated with an increase in VO_2 max and with muscle fiber type (Ahmetov et al. 2009). Variation in this polymorphism is also associated with recurrent pregnancy loss (Su et al. 2011). Finally, as is true of VEGF, osteonecrosis of the femoral head has been associated with VEGFR2 genotype (Hong et al. 2010) likely as a result of the importance of angiogenesis to bone repair.

VEGFR2 genotype is associated with several additional diseases; however, whether the mechanism involved is angiogenesis related is uncertain. For example, the V297I variant is associated with atopy (Park et al. 2006), especially in combination with TNF genotype (Park et al. 2007) as well as with hemorrhagic stroke (Zhang et al. 2009). VEGFR2 SNPs are also associated with sarcoidosis (Pabst et al. 2010), coronary artery disease in both normal individuals (Wang et al. 2007) and in Kawasaki disease patients (Kariyazono et al. 2004), and saphenous vein graft patency (Ellis et al. 2007), underlining the importance of the VEGFR2 gene in atherosclerosis.

HIF-1 α

HIF-1 α is a transcription factor that is involved with major cellular oxygen sensing pathways. In hypoxia, the protein is stabilized and up-regulates genes involved in erythropoiesis and angiogenesis such as erythropoietin, adrenomedullin, and VEGF. The oxygen sensitivity of this response can vary widely between individuals (Brooks et al. 2009) and two polymorphisms in the gene appear to affect function

M.S. Rogers and R.J. D'Amato

(P582S rs11549465 +1772C > T and A588T rs11549467 +1790G > A) by increasing protein levels and transcriptional activity (Tanimoto et al. 2003). The functional nature of these alleles is underlined by repeated reports that they are overrepresented in high-performance athletes and their association with maximal exercise-induced oxygen consumption.

Interestingly, although there are only a few positive reports of association between HIF-1 α polymorphisms and cancer incidence, there are repeated reports in multiple tumor types of association with tumor size and disease aggressiveness (Zhao et al. 2009). Interestingly, the A588T polymorphism is associated with gastric cancer in Tibetans (Li et al. 2009a). Importantly, this group shows a high frequency of alleles that alter HIF-1 α regulation and are believed to contribute to high-altitude adaptation (Simonson et al. 2010). Thus, this association may only have relevance to this population.

The P582S polymorphism is associated with an increase in coronary collateral arteries (Resar et al. 2005) and thus cardiovascular disease patients with this genotype tend to present with stable angina rather than acute myocardial infarction (Hlatky et al. 2007). In contrast, in hemodialysis patients, polymorphisms are associated with acute myocardial infarction and hypotension (Zheng et al. 2009). It is also associated with susceptibility to systemic sclerosis, a disease characterized by vascular inflammation and angiopathy (Wipff et al. 2009). Finally, distinct polymorphisms of unknown significance are associated with osteonecrosis of the femoral head (Hong et al. 2007).

Nitric Oxide Synthase (NOS3/eNOS)

Nitric oxide is a multipotent signaling molecule with significant effects on angiogenesis, vasodilation, vascular permeability, and inflammation. In addition, as a free radical it has significant mutagenic potential. Endothelial nitric oxide synthase (eNOS/NOS3) is the major endothelial producer of nitric oxide. Three polymorphisms in NOS3 have been well studied: -786T > C in the promoter, a variable number tandem repeat in the fourth intron,

and 894G > T in exon 7 which results in an amino acid change (E298D) in the protein. All of these polymorphisms can affect eNOS activity (Wang et al. 2000; Marangoni et al. 2008). Although the polymorphisms were initially identified in the context of cardiovascular disease, they have also been associated with several angiogenesis-dependent diseases. Because the E298D polymorphism has been associated with differences in collateral formation (Lambdin et al. 2005), angiogenesis may be the mechanism by which this polymorphism affects a subset of cardiovascular disease.

Retinopathy of prematurity is associated with all three polymorphisms (Rusai et al. 2008; Yanamandra et al. 2010), whereas the coding polymorphism affects endometriosis (Kim et al. 2009a), and the promoter polymorphism affects idiopathic osteonecrosis of the femoral head (Glueck et al. 2007).

In cancers such as non-small cell lung cancer (Fujita et al. 2010), acute lymphoblastic leukemia (ALL), and breast cancer there is evidence to suggest that NOS3 mutations can affect disease susceptibility (Haas et al. 2009; Hao et al. 2010; Zintzaras et al. 2010). Such susceptibility might be a result of increased angiogenic activity and a consequently decreased threshold for the angiogenic switch. In addition, increased free-radical production might increase the mutation rate in a tissue, thereby increasing the rate of cancer formation. This possibility is highlighted by reports of an interaction between NOS3 genotype and antioxidant consumption in the risk of breast (Li et al. 2009b) and prostate (Lee et al. 2009a) cancers. In contrast, progression to advanced disease and metastasis are necessarily angiogenesis dependent. Thus, it is interesting to observe that in several cancers the genotype is not significantly different between controls and patients; however, if one focuses on early progression, metastasis, and/or disease-free survival following treatment there is a correlation with genotype.

Finally, there is also evidence that NOS3 polymorphisms can influence response to and side effects from cancer therapy. In ALL the amino acid polymorphism can affect a patient's IQ following cranial radiation (Krajinovic et al.

2005). Similarly, in the breast cancer setting, a reduced incidence of radiation-induced telangiectasias was noted in women with lower-activity NOS3 genotypes (Kuptsova et al. 2008). In NSCLC a decreased risk of pneumonitis was noted in carriers of the low-activity E298D allele (Hildebrandt et al. 2010); however, that effect is almost certainly not attributable to differences in angiogenesis, but rather to inflammatory differences. Similarly the decreased rectal cancer survival observed in carriers of the E298D allele following radiotherapy (Funke et al. 2009) are likely a result of decreased low reactive oxygen production rather than any angiogenic effects.

Integrins

Several integrins are expressed on endothelial cells, including $\alpha v \beta 3$, which is upregulated in the angiogenic endothelium. During angiogenesis, this complex interacts directly with VEGFR2 and PDGFR β and cooperates with VEGFR2 to stimulate endothelial cell migration. An early study showed that the $\beta 3$ integrin L33P polymorphism increased the risk of melanoma as well as ovarian and breast cancers (Bojesen et al. 2003). In the case of breast cancer, this risk appears to be particularly strong for younger women (Wang-Gohrke and Chang-Claude 2004) and extends to the risk of metastasis (Ayala et al. 2003; Langsenlehner et al. 2006). Polymorphisms in αv integrin have been implicated in susceptibility to hepatitis B virus induced hepatocellular carcinoma (Lee et al. 2009b) and regional spread in gastric cancer (Scartozzi et al. 2010). Other integrins (e.g., $\alpha v \beta 5$, $\alpha 5 \beta 1$) are also expressed on endothelial cell and involved in angiogenesis, but studies have not identified polymorphisms in these genes that regulate angiogenesis or angiogenesis-dependent disease.

IL-8/CXCR2

IL-8 is a VEGF-independent stimulator of angiogenesis which acts through the receptors CXCR1 and CXCR2, with the latter being the endothelial receptor (Li et al. 2003). The IL-8 -251T > A polymorphism leads to increased

IL-8 production (Hull et al. 2000) and increases plasma IL-8 levels (Lee et al. 2005).

There have now been over 50 studies conducted to assess the relationship between the IL-8 -251A allele and cancer. A meta-analysis of these studies found that the A allele increases the risk of nasopharyngeal carcinoma and that it increased the risk of a group of "other" less studied cancers (Gao et al. 2010). Importantly, when studies with population-based controls were compared with those with hospital-based controls it was found that hospital-based controls indicated an increased risk of cancer, whereas population-based controls indicated a decreased risk of cancer from the A allele (Gao et al. 2010). This result suggests that overall health status may be affected by an individual's IL-8 allele and, thus, the immune functions of IL-8 may confound the ability to detect differences in cancer resulting from angiogenic differences. In this context, the effect of the A allele on tumor recurrence may be instructive. In stage III colon cancer recurrence is predicted by the high expressing A allele (Lurje et al. 2008), as is recurrence in rectal cancer (Gordon et al. 2006). This allele also predicts incidence, recurrence, and overall survival in gastric adenocarcinoma (Lurje et al. 2010a) and increased risk of and aggressiveness in breast cancer (Snoussi et al. 2010). Interestingly, this polymorphism also represents a pharmacogenomic marker in anti-angiogenic therapy. It is associated with lower response to bevacizumab and metronomic cyclophosphamide in ovarian cancer as is the CXCR2 +785C > T polymorphism (Schultheis et al. 2008). At the distinct CXCR2 +1208C > T polymorphism, the TT genotype is associated with both incidence and aggressiveness in breast cancer (Snoussi et al. 2010).

Proteases and Protease Inhibitors

Several proteases, including matrix metalloproteinases (MMPs), their tissue inhibitors (TIMPs), and members of the plasminogen system, are known to be involved in the invasion and remodeling required for angiogenic vessel outgrowth. In addition to remodeling matrix, some proteases and inhibitors have more direct

M.S. Rogers and R.J. D'Amato

activities. For example, the plasminogen fragment angiostatin has antiangiogenic activity (O'Reilly et al. 1994). Similarly TIMP-3 antagonizes VEGF binding to VEGFR2 (Qi et al. 2003) and inhibits endothelial chemotaxis, collagen gel invasion, and vessel growth in the CAM assay (Anand-Apte et al. 1997). Certain loss-of-function mutations in TIMP-3 result in Sorsby's fundus dystrophy, decreasing the antiangiogenic properties of Bruch's membrane and increasing susceptibility to choroidal neovascularization (Weber et al. 1994). Similarly, susceptibility to age-related macular degeneration is affected by polymorphisms in the TIMP3 gene (Chen et al. 2010b). Longer length in an MMP9 promoter microsatellite is also associated with susceptibility to wet ARMD (Fiotti et al. 2005). In men with proliferative diabetic retinopathy the MMP2 -1306C allele is associated with higher plasma MMP2 levels and with disease (Beranek et al. 2008) and the similar -735C > T polymorphism is associated with psoriasis (Vasku et al. 2002). In these diseases, it seems likely that gene polymorphism modulates disease susceptibility by modulating the angiogenic response, although other mechanisms are possible. Polymorphisms in several of these genes are also associated with cancer; however, in all of these cases, because substantial tissue remodeling is a hallmark of neoplastic disease it is difficult to determine whether disease susceptibility is mediated by increased angiogenesis, increased tissue remodeling, or both.

Promising Candidates

Adrenomedullin is a potent vasodilator and a pro-angiogenic factor (Martinez 2006). An in/del in the 3' UTR of the adrenomedullin gene is associated with progression-free survival in bevacizumab- and cyclophosphamide-treated ovarian cancer (Schultheis et al. 2008). Interestingly, this polymorphism is also associated with hypertension (Ishimitsu et al. 2001), a common side effect of anti-VEGF therapy.

Full-length galectin-3 is involved in a number of processes important to tumorigenesis including anchorage independent growth and

tumor cell proliferation. The protein is also cleaved by MMPs and the cleaved form is involved in chemotaxis and angiogenesis. A P64H polymorphism adjacent to one of the MMP cleavage sites (between A62 and Y63) affects cleavage efficiency and angiogenesis stimulatory activity (Nangia-Makker et al. 2010). The H allele, which results in greater angiogenesis, is more common in Caucasian women than in Asian woman and has been hypothesized to explain a portion of the increased risk of breast cancer in Caucasian women (Balan et al. 2008). The H allele also increases the risk of breast cancer in each population independently (Balan et al. 2008).

Proteinase-activated receptor 1 (PAR-1) has been shown to regulate the differential release of pro- and anti-angiogenic factors from platelets (Ma et al. 2005; Italiano et al. 2008). A promoter in/del at position -506 in the gene is associated with outcome in gastric cancer patients (Lurje et al. 2010a) and with tumor recurrence in esophageal carcinoma (Lurje et al. 2010b).

GENOME-WIDE ASSOCIATION STUDIES IN HUMANS

In principle, genome-wide association studies for polymorphisms affecting conditions such as cancer or cardiovascular disease might discover angiogenesis response alleles. There are at least two potential examples of this. First, there have been repeated reports of genome-wide association between cancer and SNPs near the fibroblast growth factor receptor 2 gene (FGFR2) (Easton et al. 2007; Hunter et al. 2007; Thomas et al. 2009; Gaudet et al. 2010; Turnbull et al. 2010; Li et al. 2011), with the risk allele increasing the expression of the gene (Meyer et al. 2008). Overlap between array CGH-determined CNV suggests that several bFGF QTLs may be regulated by copy-number variation alleles (Cho et al. 2006). This protein is the receptor for several fibroblast growth factors, including FGF2, a powerful angiogenesis stimulator (Shing et al. 1984; Klagsbrun and Shing 1985). A similar case is that of the phospholipase PLCE1, an intracellular regulator of

growth factor signaling in both endothelial and other cell types, including cancer cells. An amino acid substitution in this gene is associated with esophageal squamous cell carcinoma in Chinese subjects (Wang et al. 2010a). The relevance of both of these findings to angiogenesis is questionable because both proteins are also mitogens and can confer survival signals. Nevertheless, it is interesting that polymorphisms in these genes, rather than others with similar characteristics, are observed to increase the risk of cancer. Thus, one might hypothesize that both the mitogenic and angiogenic activities of these proteins are involved in conferring susceptibility to cancer. Indeed, it is possible that some of the genes and regions currently identified as cancer risk alleles have as-yet undiscovered roles in angiogenesis.

A simpler case involves the HTRA1 gene in age-related macular degeneration (ARMD). HTRA1 is a serine protease expressed in the retinal pigment epithelium. It has been shown to selectively cleave eight RPE proteins. These include several ECM proteins that might regulate angiogenesis, such as fibromodulin, clusterin, ADAM9, and vitronectin (An et al. 2010). Promoter polymorphisms in HTRA1 have been associated specifically with wet ARMD (Dewan et al. 2006) suggesting that increased expression of this gene results in increased susceptibility to angiogenesis in the retina. However, the polymorphisms involved are part of a haplotype that also results in loss of function in the ARMS2 (LOC387715) gene, and this loss appears also to be required for ARMD susceptibility (Yang et al. 2010).

The absence of obvious angiogenesis-related gene associations in GWASs of diseases that are clearly angiogenesis dependent might be explained in a number of ways. First, there remains a substantial amount of “dark matter” in genetics. That is, loci identified by current GWASs and family studies explain only a small fraction of observed heritability (Manolio et al. 2009). It may be that angiogenesis response alleles substantially lie in the “dark matter.” In this context it should be noted that the design of current GWASs has resulted in enrichment for genes active very early in tumor

initiation, which thus confer susceptibility to both pre-cancerous (and pre-angiogenic) lesions and frank cancer (Varghese and Easton 2010). As outlined above, candidate gene studies have often found that angiogenesis gene polymorphisms exhibit stronger effects on tumor progression or metastasis than in tumor incidence. Thus, as GWASs move toward more refined comparisons, it is likely that angiogenesis genes will appear in greater numbers. Indeed, because cancer susceptibility results from the interplay of a large number of different processes, one means of identifying risk alleles is to use intermediate phenotypes that are affected by a smaller number of processes, thus limiting the diluting effect of other processes (e.g., apoptosis susceptibility). Second, the involvement in a wide variety of processes critical to life may limit the extent to which variation in angiogenesis-regulating genes is evolutionarily permitted. This, in turn, will limit the relative risk attributable to any given allele, and thus the detectability of that allele. Finally, current GWASs rely heavily on a tag SNP approach. Although current knowledge necessitates such an approach, it is likely to be less effective than a function SNP approach. It is thus to be anticipated that, as GWAS techniques are refined, angiogenesis-regulating genes will appear with greater frequency in the results of such studies.

LOCI IDENTIFIED IN ANIMAL STUDIES

Several experiments in rodents, designed to map tumor-related traits, have identified loci that affect angiogenic response (Table 2). For example, in the estrogen-induced pituitary tumor model, a locus on rat chromosome 5, *Edpm5*, affects tumor mass and vascularity and is associated with the switch to the angiogenic phenotype (Pandey et al. 2004). Similarly, decreased proliferative capacity and altered latency associated with altered angiogenesis have been observed in MMTV-PyMT mice with specific genotypes at any of three loci: *Mmtg1*, *Mmtg2*, and *Mmtg3* (Le Voyer et al. 2001). In addition to altering growth or latency characteristics, differences in angiogenic responsiveness

Quantitative trait loci (QTLs) for differences in angiogenic responsiveness along with their peak chromosomal location (P, proximal third; M, middle third; D, distal third), effect of the paternal (strain listed second) allele, and cross(es) in which the trait segregates.

^aMS Rogers, AE Birsner, and RJ D'Amato, unpubl.

^bMS Rogers, V Boyartchuk, AE Birsner, et al., unpubl.

may alter tumor shape or eccentricity. This may result when in a given region of a growing tumor the fraction of angiogenic tumor cells drops below the threshold necessary to maintain angiogenesis (Udagawa et al. 2002). When this occurs, the tumor ceases to grow locally, resulting in alteration of tumor shape. Thus, several lung tumor shape-determining loci (*Ltsd*) may also be angiogenesis-response loci (Tripodis and Demant 2003).

We have used the mouse corneal micropocket assay (Rogers et al. 2007) to identify several quantitative trait loci (QTLs) that control response to bFGF and/or VEGF. Importantly, these studies contrast with knockout studies because the variation underlying the trait has survived the rigors of inbreeding and the breeding requirements of colony maintenance. As a result, it is likely to more closely model common human polymorphisms that are responsible for the bulk of human disease than would other approaches. We have found results of the corneal micropocket assay to be stable with regard to animal age and cage environment, with two studies showing that genetic differences explain more than 20 times the variance that is explained by environmental factors (Rogers et al. 2003, 2004).

We have used the BXD (C57BL/6J x DBA/2J) recombinant inbred strain cross to identify bFGF response loci. As a result, we identified loci on chromosome 4, 13, 15, and 18 which we named *AngFq1-AngFq4* for angiogenesis in response to bFGF (Rogers et al. 2004). Each of these loci has been confirmed with a congenic animal from the genome-tagged mouse set (Iakoubova et al. 2001). In addition, earlier mapping studies using F2 crosses between 129P3/J, 129P1ReJ, or SJL/J and C57BL/6J identified four QTLs, one each on chromosomes 7, 12, 14, and Y (*AngFq5-AngFq8*). In the case of *AngFq5*, congenic animal generation combined with haplotype mapping identified the pink-eyed dilution mutation as a candidate that might explain the phenotype. This candidate was confirmed using the distinct pJ allele in the same gene. Thus, unexpectedly, pink-eyed dilution was identified as a gene that affects angiogenic responsiveness.

In the case of VEGF, mapping using the BXD strain set resulted in the identification of two QTLs, *AngVq1* in the middle of chromosome 10 and *AngVq2* in the proximal portion of chromosome 2, each of which has been confirmed with a GTM mouse (Rogers et al. 2003; Rogers and D'Amato 2006). Importantly, a comparison of angiogenic response to bFGF and VEGF in the BXD strain set demonstrated substantial correlation. This may be a result of the observation that a substantial fraction of bFGF response can be inhibited by a VEGF inhibitor, indicating that a portion of the bFGF response is mediated by VEGF. Subsequent work with the AXB and BXA strain sets as well as with chromosome substitution strains (Hill et al. 2006) has resulted in the identification of a second QTL on chromosome 10 (*AngVq3*) as well as QTLs on chromosomes 7 (*AngVq4*) and Y (*AngVq5*). Subsequent mapping work has identified the albino mutation in tyrosinase as responsible for *AngVq4* (MS Rogers, AE Birsner, and RJ D'Amato, unpubl.). Thus, in at least two cases, coat color loci can affect angiogenic response, indicating an overlap in the two pathways.

In addition to corneal angiogenesis, we have also extended this work to identify QTLs that control the neovascular area in a laser-induced mouse model of age-related macular degeneration (Nakai et al. 2009). In this case, because retinal pigmentation affects the amount of laser energy deposited, pigmentation-related alleles had to be controlled for. This mapping confirmed *AngVq1* and *AngVq2*. It also resulted in the identification of two new QTLs, *AngCNVq1* and *AngCNVq2* on chromosomes 2 and 19, respectively.

In addition to angiogenesis response QTLs, other QTLs affect the vasculature in inbred mice. For example, the extent and remodeling of collateral arteries are genetically controlled traits that can affect the outcome of ischemic injury (Wang et al. 2010b). Intestinal lymphatic vasculature can be affected by a QTL on chromosome 3 that includes the VCAM1 gene (Jurisic et al. 2010), and both basal and induced corneal lymphatics differ among mouse strains (Nakao et al. 2010). These traits appear,

M.S. Rogers and R.J. D'Amato

however, to be both mechanistically and genetically distinct from angiogenic responsiveness.

CONCLUSIONS

The study of the role of genetic variation in the angiogenic response is currently in its infancy. Nevertheless, it is now clear that polymorphisms in angiogenesis-regulating genes can affect a large number of phenotypes, including a wide variety related to disease processes in man. In none of these cases does an absence of association necessarily imply that the gene/protein in question is not involved in disease. Rather, it may simply mean that functional polymorphisms in the gene have not been identified or do not exist at sufficient frequency in the study populations. Importantly, odds ratios for disease susceptibility in angiogenesis-regulating genes tend to be low, with meta-analysis typically demonstrating odds ratios in the 1.1–1.3 range. This is likely to be a result of purifying selection. Nevertheless, the large number of angiogenesis-regulating genes currently identified means that, even assuming no epistatic interaction among polymorphisms, the overall risk due to angiogenesis-regulating polymorphisms could be quite high. Epistatic interactions among members of interacting pathways may substantially increase risk. Indeed, the few studies that have looked at multiple angiogenesis-regulating polymorphisms have found odds ratios associated with three risk alleles to be in the six to seven range for susceptibility (a range that would be expected to have required approximately 15 risk alleles without epistatic interactions) and 20 for tumor aggressiveness (Gerger et al. 2007; Sfar et al. 2009). Given the pervasive epistasis found in other studies of complex traits (Shao et al. 2008), it is likely that the sum of angiogenic response alleles plays a major role in angiogenesis-dependent disease. Combined with the number of angiogenesis-regulated diseases and traits, it is not surprising that polymorphisms in just one angiogenesis regulator are associated with human lifespan (Del Bo et al. 2008), and it is likely that the sum of angiogenesis-regulating variation plays a major role in determining the length and quality of life.
