The sensitive and broadly reactive character of the innate immune system makes it liable to activation by stress factors other than infection. Thermal and metabolic stresses experienced during the transplantation procedure are sufficient to trigger the innate immune response and also augment adaptive immunity in the presence of foreign antigen on the donor organ. The resulting inflammatory and immune reactions combine to form a potent effector response that can lead to graft rejection. Here we examine the evidence that the complement and toll-like receptor systems are central to these pathways of injury and present a formidable barrier to transplantation. We review extensive information about the effector mechanisms that are mediated by these pathways, and bring together what is known about the damage-associated molecular patterns that initiate this sequence of events. Finally, we refer to two ongoing therapeutic trials that are evaluating the validity of these concepts in man.

The innate arm of the immune system is geared to rapidly react with broad groups of invasive pathogens but is also triggered by a variety of physical and metabolic insults. The response consists of soluble and cellular mediators of inflammation, which resolve once the threat has been eliminated. However, failure of this response to resolve can result in chronic inflammation, loss of tissue parenchyma and development of tissue fibrosis. The presence of foreign antigen stimulates a more specific pattern of clonal expansion and affinity maturation by cells of the adaptive immune system, the recruitment of which is enhanced by the innate response. Thus the ability to acquire long-lasting immunity mediated by high-affinity T- and

B-cell receptors with exquisite sensitivity for antigenic peptides is an integrated response between innate and adaptive arms of host defense.

Whereas the adaptive system ever changes with lifetime experience of infection, the innate response is fixed by evolution. The innate system is directed against shared pathogenic sequences that often include carbohydrate and lipid moieties. A set of pattern-recognition receptors that engage with these ligands is found on tissue-resident and migratory cells. They are also present on antigen-presenting cells, T cells, and B cells. These innate receptors can detect pathogen- or damage-associated molecular patterns. Other innate receptors may detect second signals amplified by the complement and co-

C.A. Farrar et al.

agulation cascades. In effect, tissue cells and infiltrating leukocytes are “hard-wired” to sense potentially dangerous signals in the local environment and accordingly can initiate intracellular signaling pathways that mobilize the inflammatory and immune responses.

The complement and toll-like receptor (TLR) systems are well-characterized components of innate immunity. Their involvement in transplantation offers insight into the general principles outlined above. In addition, they illustrate how the innate immune response is layered into soluble and cellular components that integrate to provide immune surveillance at critical tissue sites. The purpose of this article is to understand how and to what extent these innate pathways can influence graft dysfunction and rejection. We shall also address whether manipulation of specific components at defined cellular locations can steer the response towards graft acceptance. A current perception of how these two pathways could interact is shown in Figure 1.

THE COMPLEMENT SYSTEM AND ITS ROLE IN ORGAN AND CELL TRANSPLANTATION

Complement proteins are expressed throughout the animal kingdom and function in antimicrobial defense. The pivotal protein C3 has a highly conserved thioester group, which enables covalent binding of the activated molecule on pathogen surfaces and elimination by phagocytic cells with receptors for activated C3. Covalently attached C3 also acts as a focal point for the conversion of C5 into an active form leading to the assembly of membrane attack complex, C5b-9 as lethal pores in the pathogen surface. These three basic mechanisms, namely the marking of cells for disposal, pore formation liberation of the proinflammatory fragments C3a and C5a, account for much of the injury to host tissue when the complement control mechanisms are overwhelmed or are defective. Injury of mammalian cells can therefore be related to direct membrane injury caused by C5b-

Figure 1. Pathway of injury mediated by innate immune receptors. Toll-like receptors (TLR) are pattern-recognition receptors (PRR) that sense damage-associated molecular patterns (DAMPs). Complement receptors (CR) are PRR that sense complement effector molecules (e.g., C3a, C5a, C3b, iC3b, C3d) generated by DAMP-mediated activation of complement. Stress-induced signaling through PRRs on resident tissue cells and infiltrating leukocytes mediate tissue injury, and on antigen-presenting cells and T cells promote the donor-specific immune response. Effector responses against donor antigen are also PRR-signal dependent. Cross talk between CR and TLR may alter the cellular response in a complex biological system.

9, or to cell activation mediated by specific receptors for C3a and C5a (C3aR and C5aR), or to interaction with leukocytes that have receptors (CR1-4) for the fragment C3b and its inactive metabolites iC3b and C3d attached to the target cell surface (Fig. 2).

The conversion of C3 into an active form is achieved by enzyme complexes that are assembled by the classical (antibody-mediated), alternative (hydrolytically mediated), and lectin (carbohydrate-mediated) pathways. There is much overlap in the molecular signatures that initiate these pathways. For example, the classical pathway may be triggered by nonimmunoglobulin immune surveillance molecules such as C-reactive protein (Kaplan and Volanakis 1974) and serum amyloid P (Ying et al. 1993). Carbohydrate residues on IgA and IgM molecules may trigger the lectin pathway (Zhang et al. 2006; Shi et al. 2009). The alternative pathway is constantly “ticking over” and may serve to amplify the amount of C3 that is deposited after classical or lectin pathway activation. Precise identification of the relevant pathways may therefore be problematic and, in any case, it may be suboptimal to inhibit just one of these pathways for therapeutic purposes.

Regulators (e.g., CD35, CD46, and CD55) that disrupt the stability of the converting enzyme complexes and consequently limit the cleavage of C3 on cell surfaces are cell protective. Genetic or acquired defects in the function of these regulators can lead to inappropriate activation of complement. Such defects underpin common disorders in which inflammation and immunity play a role (Walport 2001a,b). Complement-mediated injury can therefore result from undue stimulation of the pathways that activate C3 or defective regulation of C3 cleavage, or both.

Local production of complement proteins by many types of tissue-resident cells and infiltrating leukocytes can enhance the functions of innate immunity in health and disease. As a measure of this local capacity, intrarenal synthesis of C3 largely by proximal tubular epithelial cells (PTECs) contributes up to 15% of the circulating pool, the remainder of which is mainly generated by the liver (Tang et al.

1999). Damage or pathogen-related stress is a potent stimulus to this tissue production, increasing the number of copies of local product by several hundredfold (Springall et al. 2001; Farrar et al. 2006). Other essential components (e.g., lectin pathway proteins), are exclusively manufactured in the liver or by infiltrating macrophages.

Complement-Mediated Inflammatory Injury in the Early Course of Transplantation

Complement activation within the donor organ can occur at any stage of the transplant procedure (e.g., activation as a result of severe brain injury in the donor). However, two peaks of activity are recognized, the first coinciding with ischemia-reperfusion (I/R) injury (Farrar et al. 2006) and the second during acute rejection (Pratt et al. 2000), as outlined in Figure 3. Complement activation in the pretransplant kidney biopsy is associated with poor midterm function of the transplanted organ, suggesting a causal relationship with innate immune expression.

Animal experiments have shown a clear role for complement in organ reperfusion injury. Complement-deficient or depleted mice or rats are protected from I/R injury of native or transplanted organs, including heart (Jordan et al. 2001), lung (Eppinger et al. 1997), liver (Strey et al. 2003; Fondevila et al. 2008), intestine (Hart et al. 2005), pancreas (Tjernberg et al. 2008), and kidney (Zhou et al. 2000; Farrar et al. 2006). Loss of renal function is reduced by up to 50% in protected mice (Zhou et al. 2000). Cardiac infarct size is reduced by almost one-half (Schwaible et al. 2011). Regarding mechanism, C5b-9 is known to mediate parenchymal injury within the kidney, heart, and gut, increasing the cellular release of proinflammatory and fibrotic factors and contributing to tissue infarction. A second mechanism of toxicity involves a direct parenchymal action of C5a and an indirect effect mediated by leukocytes (Peng et al. 2012). In contrast, C3a appears to have no major impact, either in cardiac (Busche and Stahl 2010) or renal reperfusion damage (E. Asgari, pers. comm.).

C.A. Farrar et al.

Figure 2. The complement cascade. Complement is activated by three major pathways: classical, lectin, and alternative. The classical pathway is triggered by the binding of C1 to immune surveillance molecules that are attached to the target sequence (e.g., immunoglobulin, C-reactive protein (CRP), and serum amyloid protein (SAP)). The lectin pathway is initiated by mannose binding protein (MBL), which binds to carbohydrate residues on the pathogenic surface or IgA and IgM molecules. The alternative pathway is triggered by direct binding of C3b to activating surface. All three pathways progress to form enzyme complexes (classical or alternative pathway) that convert C3 and then C5 into active forms. This generates three groups of complement effectors. C3b is highly reactive and attaches to the activating surface. C3b and metabolites iC3b and C3d are ligands for receptors that are found on leukocytes and mediate inflammation, antigen uptake, and B-cell stimulation. C5b triggers the formation of C5b-9, a multimeric complex that creates a pore in the target cell membrane and induces cell activation and cell death. The small peptide fragments C3a and C5a interact with receptors on leukocytes and parenchymal cells to promote inflammation and, in the presence of foreign antigen, enhance T-cell stimulation. Regulators of complement activation are soluble (e.g., factor H) or membrane-associated, for example, CD35 (complement receptor 1, CR1), CD46 (membrane cofactor protein, MCP), and CD55 (decay-accelerating factor, DAF). The regulators bind C3b (and C4b) and increase its decay or proteolysis from the C3 and C5 convertases of the classical and alternative pathways. Factor H is unique to the alternative pathway. Other regulators inhibit the formation of C5b-9 (e.g., through binding of C3 by CD59).

Figure 3. Kidney immune activation against ischemia-reperfusion and transplant injury. Ischemic stress to the kidney induces the local synthesis and secretion of complement proteins directly by proximal tubule epithelial cells. Subsequent activation of the complement cascade leads to C3b and C5b deposition and engagement of receptors by terminal pathway effector molecules such as C5a, which signals via C5aR. Deposition of membranes attack complex (C5b-9) and engagement of C5aR by C5a can lead to PTEC activation and/or cell death. During allograft rejection, chemokines secreted by perturbed PTECs, such as TGF- β , result in an inflammatory phenotype within the interstitium, where lymphocytes, neutrophils, macrophages, and antigen-presenting cells (APCs) enter. APCs express complement components and receptors following complement activation during the inflammatory response and can enhance DC-mediated T-cell priming and the generation of T helper 1 (Th1) cells. C3a and C5a recognition by naïve Th cells can also promote their differentiation to a Th1 phenotype. TCR, T-cell receptor; MHC II, major histocompatibility complex class II.

These pathological functions of complement in I/R injury are highly dependent on local production of C3. Mice that lack the ability to produce C3 within the donor organ were resistant to renal reperfusion damage, despite abundant C3 being produced by the recipient. Graft-derived complement is thus a potential target in strategies to limit the impact on reperfusion damage. More selective blockade may be possible by targeting the relevant activation pathway, but it is often uncertain which pathway is critical. Evidence suggests the lectin pathway

plays a role in cardiac and renal models of post-ischemic injury, possibly triggered by carbohydrate motifs or binding of natural IgM to targets exposed as a result of tissue stress. This will need further resolution before committing to highly selective strategies for complement blockade.

Islet transplantation provides another example of the challenge posed by complement. Donor islets infused into the portal vein trigger the complement (and coagulation) systems (Ricordi and Strom 2004) and this is associated with marked reduction in cell mass. The pro-

C.A. Farrar et al.

tease inhibitor α 1-antitrypsin (AAT), which includes activity against the complement and coagulation systems, had a protective effect, lowering the threshold number of islets required for successful engraftment (Koulmanda et al. 2012). At present, islets from more than one pancreas are often required for successful engraftment. Experiments are in progress to determine if islet sparing can be achieved by using more specific interventions directed at the complement and coagulation cascades.

So, complement provides a common target for modifying the biological responses of donor organs and cells used in transplantation on exposure to physical and metabolic stress. One therapeutic strategy has used C3 mRNA inhibition to limit production within the donor organ. Another strategy uses a therapeutic construct that is planted in the graft to inhibit the cleavage of C3 and prevent the generation of complement effectors. Having successfully completed preclinical and phase I studies, the construct is being evaluated in a phase II efficacy trial (Smith 2002). Our interest in complement has led to the design of a new imaging ligand based on the receptor CR2 (Badar et al. 2011); this detects organ-bound C3b and provides a means to quantify and monitor the effect of therapy on this specific pathway of injury.

Impact of Complement on Cell-Mediated Graft Rejection

Complement activation is a well-known feature of cell-mediated rejection, as detected by the measurement of activation products in the peripheral blood, urine, and the graft. Large increases in complement gene expression occur within the graft and correspond to cellular infiltration (Pratt et al. 2000, 2002) and release of T-cell cytokines that are known to regulate complement transcription (Gerritsma et al. 1996).

More than 10 years ago, mouse kidney transplant experiments confirmed that local production of complement was essential for allograft rejection. Most animals transplanted with donor kidney from C3-deficient mice were found to accept the grafts for > 100 days (Pratt et al. 2002). In contrast, recipients of

wild-type organs rejected their kidney transplants rapidly, even when the recipient was complement-deficient. Heart transplant studies illustrated a similar principle using donor mice that were deficient in the complement regulator CD55. Here, uncontrolled activation of the complement cascade led to enhanced T-cell reactivity and promoted allograft rejection (Pavlov et al. 2008). These experiments highlight the requirement for complement to generate potent T-cell responses against alloantigen.

The mechanisms by which complement mediates T-cell alloreactivity have been investigated. To a large extent, C3a and C5a explain the effects of complement on the T-cell response. These small peptide fragments are usually associated with the inflammatory reaction in severe allergy or sepsis. However, C3a and C5a have also been shown to enhance the function of antigen-presenting cells (APC) (Peng et al. 2008, 2009) and T cells, providing essential costimulatory signals for donor-specific immune recognition (Lalli et al. 2008; Strainic et al. 2008). Receptor signaling induced by C3a and C5a increased the capacity of donor APC to generate Th1 response to alloantigen (Peng et al. 2008, 2009). In addition, C3a and C5a act directly on T cells increasing the differentiation of naïve T helper (Th0) cells to Th1, which mediate graft rejection. C3aR and C5aR signaling were also found to inhibit the development of T-regulatory cells, further directing the immune response down a pathway of rejection (Peng et al. 2006; Strainic et al. 2012; Kwan et al. 2013). Finally, donor parenchymal cells that are coated with complement were more strongly interactive than nonopsonized cells with donor-specific T cells, suggesting that intercell adhesion mediated by complement was an important factor for graft destruction by antigen-experienced T cells (Li et al. 2004). In principle, complement has multiple sites of interaction with the afferent and efferent limbs of the immune response that participate in graft rejection.

Further work has illuminated our understanding of which intracellular signaling pathways mediate the effect of C3a and C5a on antigen presentation. These not only include the expected effects on PI3-kinase and NF- κ B sig-

naling, which regulate MHC and costimulatory molecule expression on APC, but also negative regulation of cAMP, an intracellular second messenger with immunosuppressive actions (Li et al. 2008). Thus, both positive and negative signals within APC could transmit the effects of complement-induced signaling on the alloimmune response. In addition, it is possible that signaling via the mammalian target of rapamycin (mTOR) is induced by C5a, because the immunosuppressive effects of C5aR blockade were profoundly enhanced by rapamycin (Strainic et al. 2012). If verified, C5a blockade could provide a possible means to increase the immunosuppressive action of rapamycin.

Cell-autonomous production enhances these immunoregulatory functions of complement. For instance, APC derived from a variety of sources and species express complement components that lead to the generation of C3a and C5a (Li et al. 2011, 2012; Peng et al. 2006, 2009; Zhou et al. 2006). APC with specific complement defects were found to have low levels of MHC and costimulatory molecules on the cell surface and showed poor capacity for T-cell priming; instead these deficient APC promoted the development of Foxp3⁺ T regulatory function (Peng et al. 2006). And as already noted, donor kidney epithelial cells that express complement components normally are much better targets for donor-specific T cells. None of this is surprising given the impact of donor-derived complement on allograft rejection, at least in mice. It is as if cellular emission of complement marks out perturbed cells for the attention of the immune system.

Complement as a Marker and Activator of Humoral Rejection

The complement system was so named because it complements the ability of antibody and macrophages to clear pathogens from the blood. The effector role of complement in acute antibody-mediated rejection (AMR) is relatively well understood (Colvin and Smith 2005). Formed by classical pathway activation at the site of endothelium-bound anti-donor antibody, the terminal components C5a and C5b-

9 mediate the acute inflammatory response. Inflammation of the vessel wall together with the pro-thrombotic effects of complement stimulates the coagulation cascade, and this result in vessel occlusion and distal tissue infarction.

Capillary wall C4d is a relatively stable marker of classical pathway activity. The detection of C4d is an integral part of the Banff classification of AMR and serves as a diagnostic and prognostic aid (Solez et al. 2008). The development of a C4d-based assay offers a further step toward improved recognition in serum of pathogenic antibodies against HLA antigens. Given the mounting significance of complement-fixing antibodies in allograft rejection, accurate markers and diagnostic tests with established specificity and sensitivity are likely to be a help in future trials of complement inhibitors. One caveat however is in the context of C5 blockade, which has already shown success in the prevention or reversal of acute AMR (Stegall et al. 2011). C4d will not be directly affected by anti-C5 treatment, because it is formed upstream of C5 in the complement cascade. Therefore C4d may not be a reliable marker in every setting.

Another important observation concerns the mechanism of endothelial resistance to complement attack. "Accommodation" refers to the acquired resistance of graft endothelial cells to injury, despite the presence of pathogenic antibody and complement, as first described in ABO-incompatible transplantation (Park et al. 2003). Although the molecular basis for this resistance remains uncertain, several observers have noted that expression of CD46, CD55, and CD59 is increased in "accommodated" cardiac and renal allografts, suggesting that endothelial stability is maintained through resistance to complement and inducible cell death (Gonzalez-Stawinski et al. 2008; Griesemer et al. 2009; Tan et al. 2009). If confirmed, this would support current attempts to induce longer periods of graft acceptance by increasing the number of regulatory molecules on the endothelial surface. Targeted delivery of therapeutic complement and coagulation regulators to the vessel wall provides a feasible means to achieve this (Smith et al. 2007).

C.A. Farrar et al.

It is also conceivable that prophylactic treatment to reduce complement activation on the vessel wall may help to reduce the sensitization of the recipient against donor HLA antigen. The initiation of IgG production against donor major histocompatibility complex antigen was found to be complement dependent, in common with other IgG responses to different antigens (Marsh et al. 2001). Opsonization with C3 is known to improve antigen retention in lymphoid tissue and increases the sensitivity of B cells to antigenic stimulation (Dempsey et al. 1996), giving a plausible explanation for the effect of complement on alloantibody production. Blockade of this afferent limb of the antibody response may have value in preventing sensitization against a range of alloantigens.

THE TOLL-LIKE RECEPTOR SYSTEM AND ITS ROLE IN ORGAN INJURY AND TRANSPLANTATION

Toll-like receptors were first discovered in 1998, in mice displaying endotoxin resistance but a high susceptibility to gram-negative bacterial infection (Politorak et al. 1998). TLRs are an evolutionarily conserved group of trans-membrane proteins of which to date, 11 have been identified in humans and 13 in mice (Table 1). These innate receptors have a central role in immunity against invading pathogens by virtue of their ability to transduce signals in response to ligation of distinctive molecular motifs termed pathogen-associated molecular patterns (PAMPs). They are a major group of pattern-recognition receptors and are ubiquitous, being expressed on a host of both immune and non-immune cells (Arumugam et al. 2009). TLR-PAMP interactions lead to downstream effects such as cytokine and chemokine release and augmentation of costimulatory molecule expression (Sobek et al. 2004). All TLRs mediate signal transduction via the adapter molecule myeloid differentiation factor 88 (MyD88), apart from TLR3, which is dependent on the adapter molecule Toll/IL-1R domain-containing adapter-inducing IFN- β (Trif) and TLR4 through which signaling is dependent on both Trif and MyD88 (Robson 2009). The obser-

vation that TLRs are expressed on parenchymal cells suggests that they may have functions unrelated to immune-mediated destruction of pathogens. Indeed, it is now apparent that endogenous, cell-derived ligands (DAMPs) derived from both intracellular and extracellular sources during inflammation and tissue damage are capable of binding TLRs (Yu et al. 2010). DAMPs are released from cells and displayed on the cell surface following cellular injury such as hypoxia; therefore, under normal conditions, these molecules are not expressed and invisible to the immune system. A variety of endogenous DAMPs have been described that can engage TLRs, such as heat shock protein (Dempsey et al. 1996) (HSP60) (Ohashi et al. 2000), purines, heparan sulphate and degradation products of fibronectin, the EDA domain (Okamura et al. 2001). More recently, immune response to allografts has displayed an association of TLRs with heat shock proteins and high mobility group box 1 (HMGB1) (Kruger et al. 2010).

TLR-Mediated I/R Injury in Solid Organs

Organ procurement is often associated with a significant period of cold ischemia, which has a well-documented deleterious impact on graft survival. The period of ischemia and subsequent reperfusion leads to rapid complement activation as discussed earlier. Likewise, TLRs are rapidly upregulated during I/R injury. In animal models of renal I/R injury, in the absence of any alloimmune events, expression of both TLR2 (Shigeoka et al. 2007) and TLR4 has been characterized, with demonstrable upregulation of TLR4 in the outer medulla of ischemic kidney just 4 h postischemia, with extensive expression on proximal tubular epithelial cells (PTECs) 24 h after injury (Chen et al. 2011). MyD88-dependent signaling via TLR4 is required for full development of I/R injury as both TLR4 and MyD88 knockout mice are resistant to renal I/R injury (Wu et al. 2007). Conversely, TLR4 mediates hepatic I/R injury in an MyD88-independent fashion, showing the diversity and complexity of the signaling mechanisms in different organ models (Zhai et al. 2004). Indeed, the absence of TLR4 signal-

Table 1. TLRs—their microbial, endogenous ligands and cellular distribution

Receptor	Microbial ligand(s)	Endogenous ligands	Cellular expression
TLR1	Triacyl lipopeptides		B cells, monocytes, macrophages, and certain dendritic cells
TLR2	Peptidoglycan, zymosan, lipoteichoic acid, and glycolipids	HSP60, HSP70, hyaluronan, HMGB1	Monocytes and macrophages, mast cells and myeloid dendritic cells
TLR3	Double-stranded RNA, poly I:C	Messenger RNA (mRNA)	B cells, dendritic cells, and fibroblasts
TLR4	LPS	Fibrinogen, HSPs, surfactant protein A, b-defensin 2, hyaluronan, fibronectin extra domain A, heparin sulfate, HMGB-1	Monocytes and macrophages, mast cells, certain dendritic cells, B cells; intestinal epithelium and hepatocytes (low)
TLR5	Flagellin		Monocytes and macrophages, subset of dendritic cells; intestine
TLR6	Multiple diacyl lipopeptides on mycoplasma		B cells, mast cells, and macrophages
TLR7	Single-stranded RNA imidazoquinolines	RNA and protein complexes	Plasmacytoid dendritic cells, monocytes, and macrophages; B cells
TLR8	Single-stranded RNA imidazoquinolines and small synthetic compounds		Monocytes and macrophages; subset of dendritic cells; mast cells
TLR9	CpG oligodeoxynucleotide DNA		Monocytes, macrophages, and plasmacytoid dendritic cells
TLR10	Undefined		B cells, monocytes, and regulatory T cells
TLR11	Profilin		Kidney and urinary bladder epithelium
TLR12	Profilin		Macrophages, neurons, and dendritic cells
TLR13	Conserved bacterial 23S ribosomal RNA (rRNA) sequence		Monocytes, macrophages, and dendritic cells

Data based on Robson (2009).

ing in the donor organ is required to reduce I/R injury in a mouse liver transplantation model (Shen et al. 2007).

Mice that are either deficient for TLR2 or receive antisense TLR2 oligonucleotide therapy display significant protection from renal I/R injury (Leemans et al. 2005). This protective effect of therapeutic blockade of TLR2 is also observed after cardiac ischemia (Arslan et al. 2010). In the context of solid organ transplantation, both donor and recipient cells have the

capacity to express TLR2. Notably, ablation of the recipient pool of TLR2 alone with a therapeutic agent directed at murine TLR2 conferred protection from transplantation-associated ischemic injury in an isograft model (Farrar et al. 2012), suggesting that recipient leukocyte expression of TLR2 is an important mediator of the observed injury and constitutes a viable therapeutic target. The acute kidney injury was reduced by up to 60% in terms of renal function. The mechanism of inflammatory damage

C.A. Farrar et al.

resulting from TLR-ligand engagement is complex and not completely understood (Leventhal and Schroppel 2012). Evidence to date suggests a complex interaction between the induction of proinflammatory cytokines, complement activation, and TLR signaling. This potential cross talk between complement and TLR systems will be discussed in more detail later in this chapter.

T Cells Facilitate TLR-Mediated I/R Organ Damage

Although innate immune-driven I/R injury may develop in syngeneic grafts, ex vivo, or under sterile conditions, T cells, particularly of CD4 phenotype, are indispensable for the activation of local TLR-mediated proinflammatory immune sequel. The observation that systemic immunosuppression (CsA, FK506) attenuated peritransplant hepatocellular damage provided initial indirect evidence for T-cell involvement in the pathophysiology of organ I/R injury (Suzuki et al. 1993). Studies in T-cell-deficient (nude) and CD4-deficient mouse systems have proven the pivotal function of CD4 T cell in the process (Zwacka et al. 1997; Rabb et al. 2000; Burne et al. 2001; Shen et al. 2002). The question arises as to how T cells may function in the predominantly I/R-triggered innate response and in the absence of exogenous antigen stimulation?

The pathogenic role of T-cell costimulation was initially shown in a study in which CD28 blockade with CTLA-4Ig protected rat kidneys from local I/R damage (Takada et al. 1997). Consistent with the essential function of both CD28 and CD154 molecules to activate TLR-mediated inflammation cascade, livers in CD154 KO or CD28 KO mice and in WT mice treated with anti-CD154 or CTLA-4Ig are all protected from I/R damage (Shen et al. 2002). Indeed, Th1-type cells are critical in the process, as Stat4 KO (deficient in Th1 development) but not Stat6 KO, mice are I/R-injury resistant, whereas reconstitution of nude mice with T cells from Stat6KO, but not Stat4KO, mice restores cardinal features of IR damage (Shen et al. 2003).

Although the role of CD154 has been attributed to its costimulatory T-cell function, CD40 ligation on DC or macrophages by T-cell-derived CD154 represents, first of all, the critical activating signal to innate immune cells. It is plausible that endogenous ligands that trigger I/R injury may be insufficient to fully activate and sustain proinflammatory phenotype in I/R-stressed organ. For instance, Kupffer cells (KC) in the liver allograft may be less sensitive to TLR4 stimulation than peripheral macrophages because of the exposure to portal-drained and gut-derived endotoxin. Liver DC have also lower TLR4 expression levels and are less susceptible to LPS stimulation as compared with their spleen counterparts (De et al. 2005). In fact, conventional DC may exert immune-regulatory functions during I/R by producing IL-10 via a TLR9-mediated mechanism (Bamboat et al. 2010).

Interactions between the T-cell immunoglobulin mucin (TIM) family of costimulatory proteins constitute a novel molecular signaling pathway of T-cell—macrophage regulation at the innate—adaptive interface. Treatment of mice with anti-TIM-1 mAb ameliorates the hepatocellular damage, accompanied by decreased local neutrophil infiltration/activation, inhibition of T lymphocyte/macrophage sequestration and diminished homing of TIM-1 ligand-expressing TIM-4 cells in the ischemic liver (Uchida et al. 2010a). The induction of proinflammatory cytokine and chemokine programs was also blunted, data supported by findings from a renal I/R injury mouse model (Rong et al. 2011). The TIM-3–Gal-9, on the other hand, constitutes a “negative” T-cell costimulation signal, as TIM-3 blockade worsens tissue damage, along with increased IFN- γ and reciprocally depressed IL-10 expression in I/R-stressed organs (Uchida et al. 2010b). The PD-1 (B7)-PD-L1 (H1) “negative” T-cell pathway has been also shown to promote I/R cytoprotection (Ji et al. 2010; Ueki et al. 2011). Thus, multiple T-cell costimulatory pathways, both positive and negative, may function in a two-way traffic fashion to promote vs. inhibit TLR-dependent innate immune responses against I/R-insult (Fig. 4).

Figure 4. Liver immune activation against ischemia-reperfusion injury. The ischemia insult induces initial cell death, which results in diverse “danger” molecules, such as HMGB1, DNA fragments, and histones activating TLR4, RAGE, and TLR9 signaling on macrophages and/or dendritic cells and neutrophils. CD4⁺ Th1 effectors might also facilitate and regulate local innate immune activation via CD154–CD40, TIM-1–TIM3, TIM-4–galectin 9, and PD-L1 pathways. The proinflammatory milieu, composed of TNF, IL-1β, IL-5, IL-12, CXCL10, CCL2, CXCL8, and ROS, further activates local immune cells and recruits circulating immune cells, culminating in inflammatory reperfusion injury. HMGB1, high-mobility group protein B1; PD-1, programmed cell death 1; PD-L1, programmed cell death ligand 1; RAGE, receptor for advanced glycation end products; STAT4, signal of transducer and activator of transcription 4; Th1, T-helper type 1 cell; TIM, T cell, immunoglobulin, mucin-containing molecules; TLR, Toll-like receptor. (Image adapted from data from a review by Zhai et al. 2013.)

TLR-Mediated Allograft Rejection

TLR-mediated I/R injury is likely to increase the immunogenicity of a solid organ graft by augmentation of the inflammatory response of innate myeloid cells and lymphocytes that mediate adaptive immune responses (Fig. 1). To this end, it could be argued that TLRs have no direct effect on antigen-specific responses to solid organ transplants but merely exacerbate rejection by increasing the damage associated purely with IR events, for example, through production and interaction of TLR4 and HGMB1

(Kruger et al. 2009). However, there is growing evidence suggesting TLR can directly affect the antigen-specific immune response. TLRs have high expression on DC and ligation of DC-expressed-TLR leads to increased expression of costimulatory molecules (Medzhitov 2001). Mice deficient for the TLR signal adapter molecule MyD88 have impaired CD4⁺ T-cell function characterized by a skewing towards a Th2 phenotype following immunization with bacterial extracts (Jankovic et al. 2002), suggesting MyD88 is crucial for appropriate development of Th1 or Th2 T cells. Organ transplantation in

C.A. Farrar et al.

the presence or absence of TLR and/or specific adapter molecules required for full signaling has yielded mixed results. The absence of MyD88 prolongs skin graft survival in the minor-histocompatibility (HY) model (Goldstein et al. 2003). However, in more robust models, fully MHC-mismatched skin and cardiac transplants show impaired Th1 responses with concomitant reduction in DCs in the absence of MyD88, but with no prolongation of graft survival (Tesar et al. 2004).

Islet transplantation has provided insight as to the role of TLR4 in the rejection process. TLR4 is upregulated after islet transplantation and recipient TLR4 deficiency prolonged allograft survival (Zhang et al. 2010). The islet isolation procedure leads to increased TLR4 expression, a process that can be attenuated by prior exposure of donor islets to carbon monoxide, resulting in prolonged islet allograft survival (Goldberg et al. 2007). In attempts to elucidate how TLR-induced production of endogenous DAMPs mediates allograft rejection, breaking tolerance induced by costimulatory blockade may be just one mechanism. Tolerance to skin grafts induced by donor-specific transfusion and anti-CD154 immunotherapy can be overcome by activation of TLR using TLR agonists, thereby preventing apoptotic clearance of CD8⁺ effector T cells, which then reject the graft rapidly (Thornley et al. 2006). There is also a contributory T-regulatory element, highlighted by the observation that DAMP production during the alloimmune and concurrent TLR2 and TLR4 activation, leads to downregulation of Foxp3⁺ regulatory T-cell production (Lal et al. 2011).

CROSS TALK BETWEEN COMPLEMENT AND TLR PATHWAYS

Acute renal failure (ARF) in mice can be circumvented by blocking TLR2 (Farrar et al. 2012). The study tentatively links TLR2-mediated renal injury with complement activation as decreased deposition of activated complement component C3d was observed in the protected kidneys. The lectin complement pathway can be activated during renal I/R injury (Farrar

et al. 2009), mediated through an interaction of MBL-MASP-2 complexes bound to DAMPs that are expressed following transplantation. As the TLR system can be activated by engagement of DAMPs, one may speculate there will be a degree of cross talk between the two sets of activation pathways. Indeed, it has been suggested that the two systems may be capable of synergy (Damman et al. 2011a). MBL has been proposed as a TLR4 ligand, again indicative of close interaction between the two systems (Wang et al. 2011) and furthermore, MBL deficiency confers protection from renal I/R injury, an effect associated with lower renal expression of C3 (Moller-Kristensen et al. 2005). Mice that are deficient for both factor B and TLR2 develop severe acute renal failure even though knockout mice for the individual genes display curtailed injury (Amura et al. 2012), suggesting a protective mechanism may be mediated through either TLR2 or complement, or that there may be a regulatory link between the two pathways. Mice deficient in the membrane-bound complement regulator decay-accelerating factor (DAF, CD55) produce large amounts of pro-inflammatory cytokines in response to TLR4 agonist. In this model, regulation of TLR pathway activity by complement was completely abrogated in double-deficient mice (DAF and C3), an effect indicating strong dependence on complement activation (Zhang et al. 2007). Complement may regulate TLR4-mediated injury in the intestine where I/R injury-induced deposition of activated complement product occurs in a TLR4-dependent fashion (Pope et al. 2010).

Points at which there is cross talk between the two systems could prove attractive for designing targeted therapeutics. DAMPs, such as HGMB1 (Leventhal and Schroppel 2012) and MAP kinase (Zhang et al. 2007), may be key bridging points between the two systems. At present, no such studies in humans have analyzed the extent of cooperation between the two activation pathways (Damman et al. 2011a). However, in rodent models, targeting of DAMPs in islet allografts using a specific anti-HGMB1 or TLR has shown improved graft function and survival (Matsuoka et al. 2010).

CLINICAL RELEVANCE OF COMPLEMENT AND TLR MECHANISMS OF I/R INJURY

Hyperexpression of the molecular components of the complement and TLR pathways in human transplantation (Tang et al. 1999; Kruger et al. 2009; Naesens et al. 2009; Damman et al. 2011b) provides circumstantial evidence of their pathological relevance and also support the experimental data derived in rodent studies. However, more significant proof of their clinical importance will require specific intervention by therapeutic trial. Reassuringly, at least two such trials are in progress. One is addressing the role of therapeutic complement regulator (mirococept) in the prevention of delayed graft function (DGF) in renal transplantation—an important manifestation of ischemia reperfusion injury with implication for acute rejection rate and long-term graft survival. Another study is assessing the benefit of TLR2 blockade with monoclonal antibody (OPN-305), also in the context of DGF. These two different studies, one aimed to protect the tubular epithelium against complement and the other targeting the function of migratory leukocytes in the evolution of postischemic damage, are primarily designed to assess patient benefit through control of innate immunity. But they are also much needed to establish the validity of two target pathways that are thought to be important in human disease.

- Zhang N, Kruger B, Lal G, Luan Y, Yadav A, Zang W, Grimm M, Waaga-Gasser AM, Murphy B, Bromberg JS, et al. 2010. Inhibition of TLR4 signaling prolongs Treg-dependent murine islet allograft survival. *Immunol Lett* **127**: 119–125.
- Zhou W, Farrar CA, Abe K, Pratt JR, Marsh JE, Wang Y, Stahl GL, Sacks SH. 2000. Predominant role for C5b-9 in renal ischemia/reperfusion injury. *J Clin Invest* **105**: 1363–1371.
- Zhou W, Patel H, Li K, Peng Q, Villiers MB, Sacks SH. 2006. Macrophages from C3-deficient mice have impaired potency to stimulate alloreactive T cells. *Blood* **107**: 2461–2469.
- Zwacka RM, Zhang Y, Halldorson J, Schlossberg H, Dudus L, Engelhardt JE. 1997. CD4⁺ T-lymphocytes mediate ischemia/reperfusion-induced inflammatory responses in mouse liver. *J Clin Invest* **100**: 279–289.

The Innate Immune System and Transplantation

Conrad A. Farrar, Jerzy W. Kupiec-Weglinski and Steven H. Sacks

Cold Spring Harb Perspect Med 2013; doi: 10.1101/cshperspect.a015479

Subject Collection [Transplantation](#)

Heart Transplantation: Challenges Facing the Field

Makoto Tonsho, Sebastian Michel, Zain Ahmed, et al.

Bioethics of Organ Transplantation

Arthur Caplan

Overview of Clinical Lung Transplantation

Jonathan C. Yeung and Shaf Keshavjee

Immunological Challenges and Therapies in Xenotransplantation

Marta Vadori and Emanuele Cozzi

Clinical Aspects: Focusing on Key Unique Organ-Specific Issues of Renal Transplantation

Sindhu Chandran and Flavio Vincenti

T-Cell Costimulatory Blockade in Organ Transplantation

Jonathan S. Maltzman and Laurence A. Turka

Regulatory T-Cell Therapy in Transplantation: Moving to the Clinic

Qizhi Tang and Jeffrey A. Bluestone

Opportunistic Infections—Coming to the Limits of Immunosuppression?

Jay A. Fishman

Overview of the Indications and Contraindications for Liver Transplantation

Stefan Farkas, Christina Hackl and Hans Jürgen Schlitt

Facial and Hand Allotransplantation

Bohdan Pomahac, Ryan M. Gobble and Stefan Schneeberger

Induction of Tolerance through Mixed Chimerism

David H. Sachs, Tatsuo Kawai and Megan Sykes

Pancreas Transplantation: Solid Organ and Islet

Shruti Mittal, Paul Johnson and Peter Friend

Tolerance—Is It Worth It?

Erik B. Finger, Terry B. Strom and Arthur J. Matas

Lessons and Limits of Mouse Models

Anita S. Chong, Maria-Luisa Alegre, Michelle L. Miller, et al.

Effector Mechanisms of Rejection

Aurélien Moreau, Emilie Varey, Ignacio Anegón, et al.

The Innate Immune System and Transplantation

Conrad A. Farrar, Jerzy W. Kupiec-Weglinski and Steven H. Sacks
